Normal Values of T, B and NK Lymphocyte Subpopulations in Peripheral Blood of Healthy Cuban Adults

Elena Kokuina MD PhD, Martha C. Breff-Fonseca MD, Carlos A. Villegas-Valverde MD MS, Isabel Mora-Díaz MD

ABSTRACT

INTRODUCTION Quantiﬁcation of lymphocyte subpopulations is useful for evaluating immune response in states of health and disease, including immunodeﬁciencies, autoimmunity, infections and cancer. Studies have found that concentrations and proportions of different cell subpopulations vary with geographic location, age, sex and ethnicity. Knowing the normal values of these cells and their variation in healthy populations will contribute to improved clinical practice and scientiﬁc research.

OBJECTIVE Estimate normal absolute concentrations and percentages of the most abundant lymphocyte subpopulations in peripheral blood and their relation to sex and age.

METHODS A cross-sectional analysis was conducted in 129 healthy adults, 61 men and 68 women aged 18–80 years; 89 aged <50 years and 40 ≥50 years. We included individuals who agreed to participate by written informed consent. Exclusion criteria were chronic disease, or use of tobacco, alcohol or medications that can alter immune system cell numbers and functions.

Through dual platform ﬂow cytometry, we determined absolute and percentage values for T lymphocyte subsets CD3+, CD3+/CD4+, CD3+/CD8+, CD19+ B cells and CD3-/CD56+ natural killer cells in peripheral blood, using an 8-color ﬂow cytometer. We estimated medians and the 2.5 and 97.5 percentiles and calculated the Pearson correlation coefﬁcient to evaluate associations. Signiﬁcance tests were also used to compare groups. The signiﬁcance threshold was p = 0.05 in all cases.

RESULTS Ranges of absolute values and percentages (%) were: total lymphocytes: 1200–3475 cells/μL (20.2–49.3); CD3+ T cells: 880–2623 cells/μL (56.5–84.7); CD3+/CD4+ T cells: 479–1792 cells/μL (30.3–55.7); CD3+/CD8+ T cells: 248–1101 cells/μL (13.2–42.9); CD19+ B cells: 114–1491 cells/μL (5.4–49.5); CD3-/CD56+ natural killer cells: 70–652 cells/μL (3.7–28.0) and the CD4+/CD8+ index: 0.80–3.92. Absolute numbers—but not percentages—of lymphocytes and CD3+ T cells were higher in those <50 years (p = 0.025 and 0.020, respectively). Absolute values and relative percentages of CD3+/CD8+ and relative values of CD3+/CD4+ T cells were signiﬁcantly higher in the younger subgroup (p = 0.004 and p = 0.047). Age was not associated signiﬁcantly with B lymphocytes or natural killer cells. Absolute and relative values of CD3+/CD4+ T lymphocytes were signiﬁcantly higher in women (p = 0.009 and 0.036, respectively).

CONCLUSIONS Absolute numbers of total lymphocytes and T and CD3+/CD8+ T lymphocytes are higher in younger individuals. In percentage values, CD3+/CD4+ T lymphocytes are lower in older persons. Absolute and percentage values of CD3+/CD4+ T phenotype are higher in women. These differences justify adjusting clinical analyses to different values by age and sex.

KEYWORDS T lymphocytes, B lymphocytes, normal values, ﬂow cytometry, age, sex, Cuba

INTRODUCTION Quantiﬁcation of lymphocyte subpopulations by ﬂow cytometry is considered the most exact and reliable procedure to assess immunocompetence, which allows the body to maintain homeostasis against invading pathogens and the body’s own damaged cells. Numerous diseases are associated with alterations in peripheral blood lymphocyte subpopulations, including primary or congenital immunodeﬁciencies, in which certain lymphocyte subpopulations are absent or reduced; secondary immunodeﬁciencies including HIV infection, which destroys the CD4+ T cell subpopulation; systemic autoimmune diseases; infections; and cancer. Quantiﬁcation of lymphocyte subpopulations is necessary in these clinical conditions to establish diagnosis, and as a criterion of disease progression and treatment optimization.[1–3] Socioeconomic and sociodemographic factors (including age and sex) and environmental factors such as exposure to infectious agents,[4–6] Interpretation of lymphocyte subpopulation data for clinical practice requires establishing normal ranges for local populations. These ranges have not been deﬁned for the Cuban population.

The study objective was to estimate absolute and relative values of peripheral lymphocyte subpopulations of CD3+, CD3+/CD4+, CD3+/CD8+ T cells, CD19+ B cells, CD3-/CD56+ natural killer cells, the CD4+/CD8+ index and the variation in their distribution by age and sex in healthy Cuban adults.

METHODS Design, subjects and sample A cross-sectional study was conducted from January through April 2017 in 129 healthy adults, 61 men and 68 women, aged 18–80 years, of whom 89 were <50 years and 40 ≥50 years. Average age was 43.5 years and 37.8 years for women. The proportion of men and women was similar in both age groups (p = 0.172). Participants were hospital workers and patient companions recruited in the clinical laboratory of the Hermanos Ameijeiras Clinical-Surgical Teaching Hospital in Havana (HCQHA), Cuba. After agreeing to participate on the basis of written informed consent, they completed a questionnaire requesting information on demographic characteristics (age, sex, and schooling), lifestyle, medication consumption and personal medical history. Subjects with the following characteristics were excluded: present tobacco or al-
Alcohol use, treatment with immunosuppressive and immunomodulatory drugs in the previous six months, pregnant women, and those with acute or chronic infectious diseases such as HIV, hepatitis B, hepatitis C and tuberculosis; chronic metabolic diseases; and cardiac, pulmonary, renal, cerebral, systemic, allergic and neoplastic autoimmune diseases.

Peripheral blood samples were obtained by antecubital venous puncture, collected in vacutainer tubes containing ethylenediaminetetraacetic acid (EDTA) as anticoagulant, and processed by flow cytometry within four hours following best laboratory practices. Absolute and differential blood cell count was calculated for all samples using an automated hematology analyzer (Horiba Medical, France).

**Flow cytometry** Lymphocyte subpopulations were determined in whole peripheral blood, lysed using a Versalyse buffer (Beckman Coulter, France) without washing. For immunophenotyping using fluorochrome conjugated monoclonal antibodies anti-CD45 AA750 (Clone J33), anti-CD19-PC7 (Clone J3-119), anti-CD3 FITC (Clone UCHT1), anti-CD4 PC5.5 (Clone 13B8.2), anti-CD8 AA700 (Clone B9.11) and anti-CD56 PE (Clone N901) (NKH-1), 100 μL of blood were dispensed. Sample preparation was carried out according to manufacturer guidelines.

Lymphocyte subpopulations were characterized by combining monoclonal antibodies for T, B and NK cells:
- T cells: (CD45+, CD3+); (CD45+, CD3+, CD4+); (CD45+, CD3+, CD8+)
- B cells: (CD45+, CD19+)
- NK cells: (CD45+, CD56+, CD3-).

Sample collection was carried out with an 8-color Gallios flow cytometer (Beckman Coulter, France), using Kaluza Acquisition software for Gallios, Version 1.0 (Beckman Coulter, France). For each sample, a minimum of 10,000 events were collected (referring to number of cells in the sample of lysed red blood cells passing the cytometer’s laser beam for counting and analysis).

In each case, more than 4,000 events were obtained in the lymphocyte gate, characterized by high expression of CD45 and low side-scatter complexity (SSC). Figure 1 shows the gate strategy with a dot plot, which starts by eliminating doublets (cells passing the interrogation point in groups), followed by a plot removing artifacts and detritus (forward scatter vs. side scatter) and from which the lymphocyte population was selected. Plots were generated from this lymphocyte region by combining two of the antigens expressed on the cell surface with separation by quadrants, allowing identification and determination of percentage of subpopulations.

Data were analyzed with Kaluza Analysis software V 1.2 (Beckman Coulter, France). Absolute counts of lymphocyte subpopulations were calculated by dual platform, from percentages obtained by flow cytometry and lymphocyte counts obtained by hematology analyzer (Horiba Medical, Montpellier, France) using the formula:

\[
\text{Absolute count (cells/μL)} = \frac{\text{Lymphocyte count (cell number/μL of the blood count) x proportion of the cell subpopulation of interest}}{100}.
\]

Internal quality control was performed daily by checking the cytometer’s optical detector and aligning lasers and fluid systems using Flow-SET Fluospheres and Flow-Check Fluospheres (Beckman Coulter, France), respectively, according to manufacturer guidelines.

**Statistical analysis** Descriptive statistics were calculated for absolute and relative frequencies, means, medians, standard deviations (SD) and reference ranges of percentage and absolute values for each cell marker. The Kolmogorov-Smirnov test was used to test the normal distribution of variables. Ref-
ference ranges were defined as 2.5–97.5 percentiles. The Student t test was applied for variables with Gaussian distribution and the two-tailed Mann Whitney U test for independent samples to evaluate the influence of sex and age on peripheral lymphocyte concentrations. Association with cell values was calculated using the Pearson correlation coefficient. The significance threshold was p = 0.05. Statistical analysis was done with SPSS v 20.0 software for Windows XP.

**Ethics** The project was approved by the HCGHA research ethics committee. All participants were asked if they were willing to participate and joined the study only after providing written informed consent, in compliance with the Helsinki Declaration.[7] The consent form explained the importance of participating, characteristics of the research, and possible risks and benefits. Data storage adhered to principles of confidentiality and data were de-identified. The selection of diagnostic means followed principles of maximum benefit, the ethics rule of do no harm, and best laboratory practices.

**RESULTS**

Means, standard deviations, medians and reference ranges of absolute values and percentages of lymphocyte subpopulations are shown in Table 1. Absolute values are expressed in number of cells per microliter and percent ranges refer to relative frequencies of each subpopulation in relation to total lymphocytes.

Table 2 shows ranges of lymphocyte subpopulations in absolute numbers, age ranges and sex composition obtained for Cuban adults in this study and in studies conducted in five countries, where differences can be observed in cell concentrations as well as technologies and platforms used.

a: median; b: median of men and women respectively; c: Interquartile range; na: not available

Percentages and absolute values of cell subpopulations were related to age. Regression analysis showed that absolute lymphocyte counts (r = -0.265; p = 0.002), CD3+ T cells (r = -0.314; p = 0.0001) and CD3+/CD8+ (r = -0.326; p = 0.0001) significantly decrease with age; while the CD4+/CD8+ index significantly increases (r = 0.263, p = 0.003)

The total number of lymphocytes and other cells in the T cell compartment were associated with age, with lower absolute values of CD3+ and CD3+/CD8+ T cells in the older age group. The CD3+/CD4+ T cell fraction had higher concentrations in participants aged ≥50 years. CD19+ B lymphocyte and CD3+/CD56+ NK cell values did not change with age (Table 3).

Absolute numbers and percentages of CD3+/CD4+ T cells were higher in women (p = 0.009 and p = 0.036, respectively). The CD4+/CD8+ index had higher values in women (p = 0.043); there were no differences by sex for CD3-/CD19+ B lymphocytes and CD3-/CD56+ NK cells (Table 4).

**DISCUSSION**

This is the first study reporting normal absolute and percentage values for T lymphocytes and their subpopulations, as well as B lymphocytes and NK cells, in peripheral blood of healthy Cuban adults. Because clinical diagnoses based on measures drawn from local populations are more reliable, the study’s results are a first step in the application of domestic data to diagnosis and clinical management of Cuban adults with diseases causing alterations of peripheral lymphocyte subpopulations.

Some authors have demonstrated the influence of ethnicity and certain sociodemographic characteristics on the composition of
lymphocyte subpopulations. Regional differences have been reported within large countries such as Brazil, China and India.[12–14] When we compare lymphocyte values between our study and those of other populations in America, Europe, Asia and Africa, differences between countries are observed which could be attributed not only to biological or sociodemographic factors such as age, sex and ethnicity, but also to environmental factors such as exposure to infectious agents, air pollution and lifestyles.[13–17] Taking into account the influence of environmental and sociodemographic factors and their changes over time, specific ranges of lymphocyte subpopulations should ideally be determined by geographically localized populations and updated through periodic re-evaluation.[11–18]

Average CD3+, CD3+/CD4+ and CD3+/CD8+ T lymphocyte subpopulations in our study are closer to those of other countries and areas of the American continent, such as south Florida (US).[17] Brazil,[8] and Peru,[9] than to those of Korea,[11] Germany,[4] Tanzania,[10] and China.[14] One explanation for differences in lymphocyte subpopulation distribution is variations in infectious agent exposure, even within the same geographic region.[15,18] The greater expansion of peripheral B cells in our study participants could be associated with the presence of arboviral diseases, especially dengue virus, in this area. Dengue virus is endemic in most tropical and subtropical regions and the vast majority of infections are asymptomatic.[20] It has been reported that individuals exposed to dengue virus have abnormally high levels of activated B cells,[21] not only due to the clonal expansion of virus specific B cells, but also to virus-induced nonspecific polyclonal activation.[22]

Reasons for decline of CD3+ and CD3+/CD4+ T cells in younger persons are still unknown; unlike CD3+/CD4+ T cells, whose values remained stable in older individuals in this study.[24] In each T cell subpopulation, naïve cell production decreases and memory-cell accumulation increases with age. But the combinations of decreased naïve lymphocyte production and the accumulation of memory cells may be different within the CD3+/CD4+ and CD3+/CD8+ subpopulations depending on total lymphocyte production and interactions with the environment over time.[28,29]

Depletion of a T cell compartment may occur at senescence in response to persistent infections. Stervbo found higher numbers of CD4+ T cells specific for cytomegalovirus (CMV) in individuals

aged 53–67 years, whereas presence of CMV-specific CD8+ T cells was not modified by age.[28] The differences in stability of the CD3+CD4+ and CD3+CD8+ T cells in relation to age could be attributed to these two subpopulations being regulated by different growth factors and cytokines.[30]

Previous studies reported a reduction in the CD4+CD8+ index with increasing age, which constitutes the Immune Risk Profile associated with morbidity and mortality in old age.[31,32] Some investigations attribute the reduction in the CD4+CD8+ index to immune response against CMV and have shown a negative association between the CD4+CD8+ index and CMV seropositivity in old age.[33] Others observe no decrease in the CD4+CD8+ index with respect to age, but do report a negative correlation between this ratio and CMV seropositivity.[29] In this study we did not find reduction of the CD4+CD8+ index in older individuals, so the decline reported in the literature could be a characteristic of older adults infected with CMV.

Comparison of lymphocyte subpopulation levels between men and women found CD3+CD4+ T cells were more numerous in women. Higher levels of this subpopulation in Cuban women in relation to men were more marked in absolute values than in the fraction of CD3+CD4+ T cells. Higher values of CD3+CD4+ cells have been observed in women compared to men in different populations of Brazil,[8] Spain,[17] Korea,[11] France,[34] Israel,[23] and India.[6] Although no differences were found in lymphocyte subpopulations between men and women in a study of the south Florida (US) population, the CD4+CD8+ index was higher in women.[18] For this to occur there should be more CD4+ cells or fewer CD8+ cells.

Absolute values of activated T cells within the CD3+ subpopulation (CD3+HLA-DR/CD25) were also higher in Cuban women.[35] Unequal distribution of lymphocyte subpopulations between men and women and in particular the higher frequency of CD4+ T cells in women may explain their greater resistance to infectious diseases and greater likelihood of developing autoimmune diseases.[36,37] The difference in values of CD3+CD4+ cells can be attributed to the effect of sex hormones on their specific receptors expressed in T and B lymphocytes.[38]

Sex chromosome genes and sex hormones such as estrogen, progesterone and androgens contribute to male/female differences in immune response.[39] Estrogen is known to enhance both cell-mediated and humoral immune responses, while androgens suppress the differentiation of Th1 cells, and reduce gamma interferon (IFN-γ) production and B-cell antibody responses.[40,41] In general, women develop stronger humoral and cellular responses than men, associated with higher levels of antibodies and other immune mediators such as IL-1, IL-4 and IFN-γ.[42] Nutrition and microbiome composition also determine differences in development and functioning of immune response in men and women.[39]

We note several limitations of our study. The sample included only residents of Havana and none from other Cuban provinces. Additional serologic studies were not carried out, leaving open a possible sub-diagnosis of chronic and infectious diseases. Absolute values were calculated on a dual platform, which could be the source of inter-laboratory variability. However, no difference has been demonstrated between single or dual platform results.[43]

It would be advisable to study peripheral B cell numbers in a larger sample of healthy Cuban individuals including different areas of the country to determine the possible relationship with regional and individual factors that may vary according to genetic ancestry, living conditions and lifestyles (e.g., nutrition, smoking) and air pollution. The composition of B cells in terms of memory cells and plasmablast proportions in Cuban individuals with high and low peripheral B cell levels should also be determined.

CONCLUSIONS

Absolute and percentage concentrations of lymphocyte subpopulations found in the Cuban sample were different from those obtained in other countries. Absolute and percentage values of the CD3+/CD4+ T phenotype are higher in women. Absolute values of total lymphocytes and of CD3+/CD8+ T lymphocytes are higher in younger participants. In percentage values CD3+/CD4+ T lymphocytes have lower values in older subjects. These differences justify adjusting clinical studies to different values by age and sex. The study supports improved diagnosis in Cuba, since it provides a new, albeit preliminary, set of reference values.
